ABSTRACT

EFFECT OF IMPELLER SUBMERGENCE ON POWER DISSIPATION AND SOLIDS SUSPENSION IN MIXING SYSTEMS EQUIPPED WITH PITCH-BLADE TURBINES

By

Yufeng Song

Mixing and dispersion of solids in a liquid is a process frequently encountered in the pharmaceutical industry and often conducted in cylindrical baffled tanks stirred by mechanical impellers. In operations where the liquid level is decreased (as often which emptying the tank) the process must be stopped when the solids are no longer suspended. In this work, the minimum agitation to suspend solids (N_{js}) when the liquid level was lowered, and the impeller submergence S_b changed as a result were determined for the case of a six-blade, pitch-blade turbine (6-PBT) impeller. The power consumed by the impeller was also measured. It was found that when a critical impeller submerge level was reached it was impossible to suspend the solids and the impeller power decreased significantly, although the impeller was still full submerged. The results are important to ensure that mixing systems are operated properly.

BIOGRAPHICAL SKETCH

Author: Yufeng Song

Degree: Master of Science

Date: May 2015

Undergraduate and Graduate Education:

Master of Science in Pharmaceutical Engineering,
New Jersey Institute of Technology, Newark, NJ, 2015

Bachelor of Science in Pharmaceutical Science,
Shandong University, Jinan, P. R. China, 2012

Major: Pharmaceutical Engineering

To My Friends

ACKNOWLEDGMENT

I owe my gratitude to all those people who have made this thesis possible and because of whom my graduate experience has been one that I will cherish forever.

My deepest gratitude is to my advisor, Dr. Piero Armenante. I have been amazingly fortunate to have an advisor who gave me the freedom to explore on my own, and at the same time the guidance to recover when my steps faltered. Dr. Armenante taught me how to question thoughts and express ideas. His patience and support helped me overcome many crisis situations and finish this thesis.

I would like to acknowledge Dr. Kamalesh Sirkar and Dr. Xianqin Wang for their patience in reviewing the thesis, for their recommendations and everything

S_b/D	Impeller submergence ratio (-)
τ	Torque (Nm)
δ_B	Gap between baffles and tank (m)

CHAPTER 1

INTRODUCTION

1.1 Background

The term “mixing” refers to all those operations that tend to reduce non-uniformity in one or more of the properties of a material in bulk (e.g., concentration, temperature). Mixing of a liquid with other media (fine solids, gas, immiscible liquid) is an extremely common operation encountered in countless applications in the pharmaceutical industry. In the pharmaceutical industry many mixing, reaction, and mass transfer operations are conducted in stirred tanks and reactors.

Stirred vessels are commonly used in industry to achieve the desired process objectives. Over 50% of chemical, pharmaceutical, and food production takes place in batch stirred-tank/reactors. Quality of mixing is important: poor mixing leads to off-spec products; both under-mixing and over-mixing must be considered.

In the industrial practice, mixing of solid in liquid is often conducted in cylindrical baffled tanks stirred by mechanical agitators. The role of baffles in a mechanically agitated vessel is to promote the stability of power drawn by the impeller and to prevent swirling and vortexing of liquid, thus, greatly improving the mixing of liquid. (Myers et al., 2002).

The performance of any mixing operation in a stirred tank/reactor is intimately related to the hydrodynamics of the liquid or multiphase system in the mixing vessel/reactor. Most tanks and reactors in industry are operated with a liquid height-to-tank diameter ratio equal to or larger than one ($H/T \geq 1$). The hydrodynamics for such systems has been extensively studied. $H/T=1$ is the H/T ratio most commonly studied for stirred tanks. However, there are many instances where $H/T < 1$. For examples, emptying/charging

batch stirred reactors and vessels, or adding reactants and solvents. The type of flow pattern observed in a stirred tank can also be affected by the impeller submergence (S_b) and the impeller submergence-to-impeller diameter ratio (S_b/D ratio), especially if the submergence is low. At low impeller submergence induced surface air entrainment may also occur, possibly resulting in impeller flooding.

Previous work was conducted by Dr. Piero Armenante's group on the effect of S_b/D on flow pattern and power dissipation for the case of a radial impeller (Disk Turbine) (Motamedvaziri, S. and Armenante, P. M., 2012). The graduate student Anqi Zhou (2013) used Zwietering's method to measure N_{js} by visually inspecting. Previous work by Armenante et al. and Armenante and Uehara Nagamine (1997,1998) determined the minimum agitation speed and power dissipation required to completely suspend solid particles in tanks provided with six-blade (45°) pitched-blade turbines impellers having small clearances off the tank bottom, and studied the effects of the impeller diameter, tank diameter, particle diameter, and physical variables. Modified correlations based on the Zwietering equation (Zwietering, 1958) were obtained to account for the effect of impeller clearance and impeller diameter-to-tank diameter ratio on N_{js} .

Geometric and operating variables have a strong impact on different mixing phenomena and mixing parameters, which have a significant effect on the process carried out in the mixing system. Chapple et al. (2002) stated that the power number is independent of blade thickness, but dependent on the impeller to tank diameter ratio (D/T). Chapple et al. (2002) also stated that the different position of the impeller in the tank can have a significant impact on the power number. Power number, Po , is one of the most important variables in the description of mixing phenomena which quantifies the power dissipated by

the impeller. The power dissipated by the agitation system is fundamental to any mixing process since energy is needed to homogenize the vessel content, disperse immiscible phases, suspend solids, increase mass transfer, and in general, produce the desired mixing effect. When the impeller submergence is reduced as a result of lowering the liquid level, the mixing performance changes depending on the geometric variables of the system (such as impeller clearance, liquid height, or liquid head above the impeller).

1.2 Objectives of This Work

The objective of this work is to study primarily the effect of S_b/D ratio, but also the effect of other geometric ratios (C_b/T , D/T), on the impeller Power Number and the minimum agitation speed for solid suspension, N_{js} , for six-blade, 45° pitch-blade turbine impellers in flat-bottomed baffled tanks and to determine the critical impeller submergence ratio (S_b/D) for adequate mixing can still be achieved. This was achieved using combinations of different impellers and tank sizes.

CHAPTER 2

EXPERIMENTAL APPARATUS, MATERIALS AND METHODS

2.1 Agitation System

The experimental apparatus, shown in Figure 2.1, consisted of a baffled cylindrical mixing tank with a flat bottom (with right-angle corner or with rounded corner; Figure 2.2), having an internal diameter, T . The tank was provided with four baffles having a width of B ($B=T/10$). The system is stirred by a single six-blade, 45° pitch-blade turbine (6-PBT; Figure 2.3) impeller having a diameter D . Tanks and impellers of different sizes were used here. Their detailed dimensions are shown in Table 2.1 and Table 2.2, respectively.

The selected impeller was mounted to a central located shaft (shaft diameter 12.52 mm) inside the tank, and was rotated by a 0.25 HP motor (Chemglass, Model CG-2033-11) controlled by an external controller (Chemglass, Model CG-2033-31). The motor was equipped with a controller to adjust the agitation speed in the range 0-500 RPM. A traversing system supporting the tank was used to change the vertical position of the tank. A data acquisition system was used to measure the agitation speed, the torque (T) applied to the impeller, and the power dissipated by the impeller. The torque applied to the impeller by the motor was experimentally measured using a strain gage-based rotary torque transducer (Model, T6-5-Dual Range, Interface, Inc., Scottsdale, AZ) mounted between the motor and the impeller. The transducer was connected to the Interface series 9850 Multi-Channel Load Cell Indicator. The transducer could measure the torque in two different ranges, i.e., 0-0.5 Nm and 0-5 Nm. The same instrument could also measure the agitation speed via a tachometer. Then the power dissipated by the impeller was calculated from:

$$P = 2\pi N\Gamma \quad (\text{Equation 2.1})$$

The indicator utilized the M700 software to interface with a computer, which was used for data acquisition and processing.

2.2 Materials

Tap water at room temperature was used as the liquid in all experiment ($\rho_L = 977 \text{ kg/m}^3$). The liquid height was equal to the tank diameter in all cases. Glass beads having average diameters of $150 \text{ }\mu\text{m}$ and $200 \text{ }\mu\text{m}$ were used as the dispersed phase ($\rho_s = 2650 \text{ kg/m}^3$). Prior to their use, the prescreened glass beads were sieved. Four US standard screens of mesh size 40, 60, 80 and 100 were selected. 30 g of glass beads were processed at a time, by placing them in the top screen with the smallest mesh size, and shaking them for five minutes. The particles retained on the size 100 mesh screen (with an average diameter size of $150 \text{ }\mu\text{m}$) and size 80 mesh screen (with an average diameter size of $200 \text{ }\mu\text{m}$) were collected separately and used in the experiments. In all experiments involving solids, the solid fraction used was 0.5% of the liquid mass (g/g).

2.3 Experimental Determination of the Power Number, Impeller Reynolds Number, and Minimum Agitation Speed

The experimental power dissipation was measured for different combinations of liquid level, impeller size, baffle tank size, impeller clearance and agitation speed. In all experiments, the system was allowed to stabilize for two minutes before collecting power data in at least 20 seconds time intervals. Equation 2.2 and 2.3 were used to obtain the experimental power number, Po , and impeller Reynold Number, Re separately.

$$Po = \frac{P}{\rho N^3 D^5} \quad (\text{Equation 2.2})$$

$$Re \equiv \frac{\rho N D^2}{\mu} \equiv \frac{N D^2}{\nu} \quad (\text{Equation 2.3})$$

Where ρ is the liquid density, N is the impeller speed (rev/sec), and ν is the kinematic viscosity of the water ($\nu = 10^{-6}$ m²/s, the testing temperature is about 20 °C).

In solid-liquid suspension studies, the minimum agitation speed for solid suspension, N_{js} , was measured visually in this work. The visual value of N_{js} was obtained using the Zwietering's criterion (Zwietering, 1958), defined as the agitation speed at which no solids remain at the tank base for more than a second or two. The corresponding power and Power Number for the suspension at N_{js} are denoted here as P_{js} and Po_{js} .

All experiments were repeated in triplicates. The power dissipation at each agitation speed was also recorded.

CHAPTER 3

RESULTS AND DISCUSSION

3.1 Effect of Impeller Submergence Ratio (S_b/D) on Power Number (Po) in Different Combination of Impellers and Stirred Baffled Tanks at $C/T=1/3$

In this portion of the work, the power number for the stirred baffled tank was obtained experimentally. The system under investigation here produced a “single loop” recirculation flow.

The impeller Power Number for Impeller #3 in Tank #3 ($D/T=0.35$) was experimentally obtained at different agitation speeds (100 – 480 rpm corresponding to Re equal to $1 \times 10^4 - 4.6 \times 10^4$) for different submergence ratio. The results are shown in Figure 3.1 (as Po vs. Re) and Figure 3.2 (as Po vs. N). From these figures one can see that Reynolds number increases with the rise in the impeller agitation speed. The Power Number is a constant when the Reynolds number is adequately high.

Figure 3.1 The relationship of power number and Reynold number at different submergence ratio (Impeller #3, Tank #3, $D/T=0.35$, $C/T=1/3$).

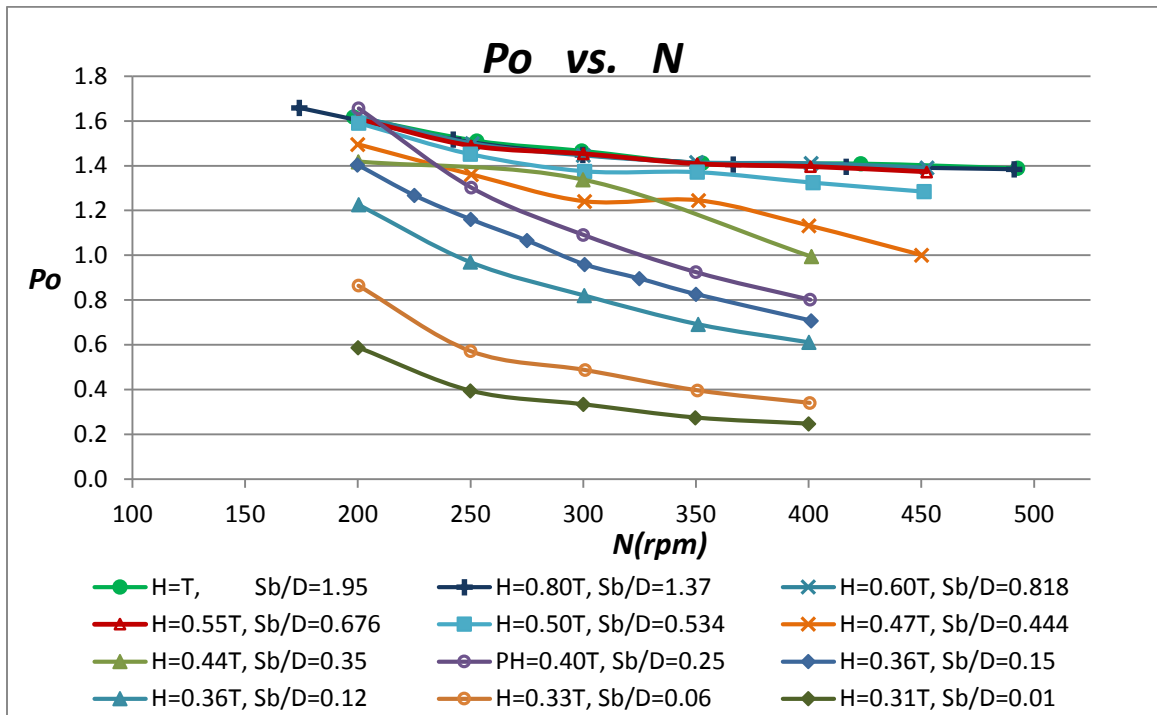

Figure 3.2 The relationship of power number and impeller agitation speed at different submergence ratio (Impeller #3, Tank #3, $D/T=0.35$, $C/T=1/3$).

Figure 3.2 shows that the Power Number is generally constant when the submergence ratio is relatively high ($S_b/D > 0.6$), i.e., when the impeller is well submerged. This can be clearly observed by examining all the power curves for high enough values of the S_b/D which are all superimposed on each other. Figure 3.3 shows a similar trend. Actual data are shown in the Appendix (Table A.1). However, when the impeller submergence ratio decreased below a critical level ($S_b/D = 0.5$ or $S_b/T = 0.2$), the Power Number decreased drastically with S_b/D . In this region, the Power Number was almost directly proportional to the submergence ratio. When the impeller operated above $S_b/D > 0.6$, i.e., just above the critical submergence ratio, no air bubbles were observed. However, when the S_b/D ratio reached a critical value, $(S_b/D)_{cr}$, at about 0.5, bubbles began becoming incorporated in the liquid. As the S_b/D ratio was further reduced more air was incorporated depending on the agitation speed. In addition, for submergence ratios lower the critical value, the Power Number decreased with increasing agitation speeds, whereas if the submergence ratio was higher than the Power number was largely independent of the agitation speed especially for higher values of N , when, in case, one would expect that aeration was more easily achieved. This can be clearly seen in Figures 3.1 and 3.2, which shows that Po is not a function of Re (or N) when $S_b/D > (S_b/D)_{cr}$, but that Po is a strong function of N when $S_b/D < (S_b/D)_{cr}$, and that Po actually decreases with increasing N values.

This phenomenon appears to be similar to that observed by Motamedvaziri and Armenante (2012) who showed that for a radial impeller there exists a critical value of the the S_b/D ratio below which the flow regime changes. Above this critical value, agitation does not affect Po . However, below this value, the flow regime changes and, if the

agitation speed is appropriately high, surface aeration starts and the Power number decreases as a result of the air incorporation in the liquid.

A similar phenomenon is likely to occur here. For $S_b/D > 0.6$, the impeller is sufficiently submerged to be “fed” from the top, resulting in the familiar axial flow associated with axial impeller. However, if the submergence is too low, the impeller is no longer able to pump effectively, and surface aeration can occur if the agitation is sufficiently high to displace the fluid surrounding the impeller radially.

Figure 3.3 show this phenomenon even more clearly. At the high agitation speed used in this figure, Po is not affected by the submergence ratio if $S_b/D > (S_b/D)_{cr}$, but it becomes a nearly linear function of S_b/D for $S_b/D < (S_b/D)_{cr}$.

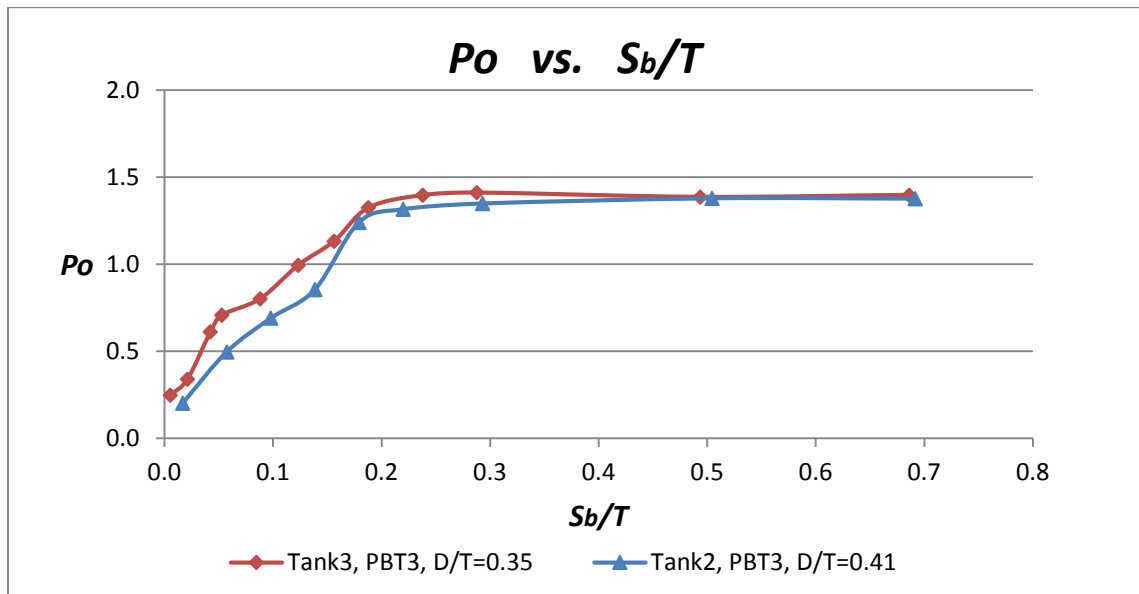

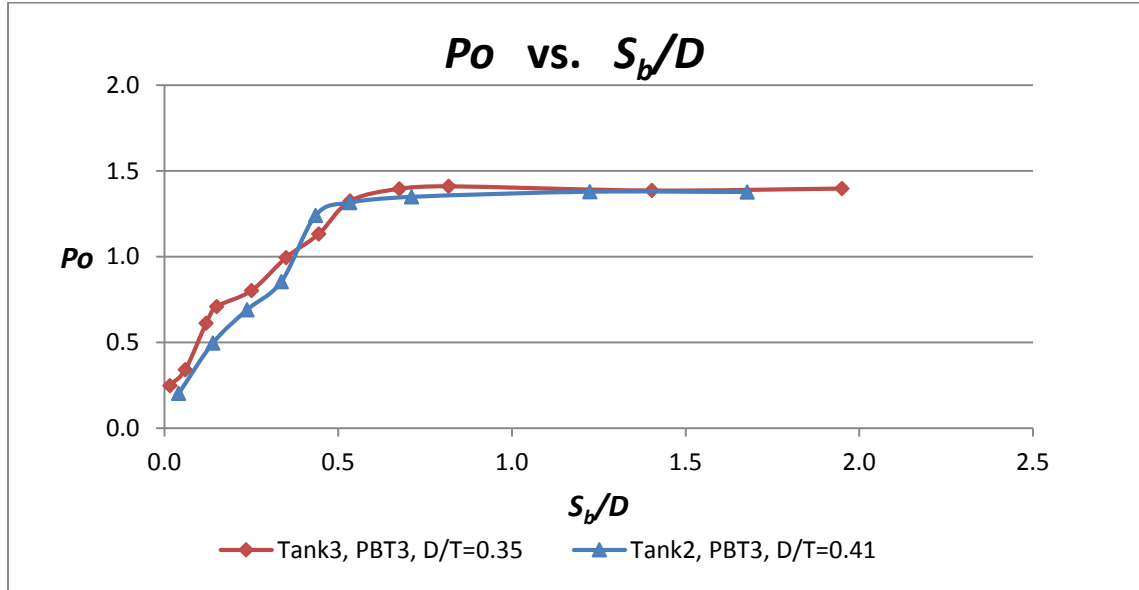

Figure 3.3 Power number, Po , for different S_b/D or S_b/T ratios in different combination of impellers and stirred baffled tanks at $C/T=1/3$ calculated from the experimental data ($N=495$ rpm).

3.2 Impeller Power Number for $H/T=1$ at Different Combinations of D/T and C_b/T Ratios

As it was discussed in the previous section, a typical axial impeller such as a pitched turbine placed in a cylindrical baffled tank filled with a low viscosity liquid typically produces a “single loop” recirculation flow. However, if the impeller off-bottom clearance (C_b) is gradually reduced, a flow pattern transition occurred.

In this section, the effect of impeller off-bottom clearance (C_b), when the H/T ratio equals to 1, mixing parameter power number was investigated. Then, for each impeller off-bottom clearance the same phenomena were examined at different impeller submergence S_b/D ratios and fill ratios (H/T).

The impeller Power Number as a function of the impeller off-bottom clearance is shown in Figure 3.4. P_o was nearly constant for impeller off-bottom clearance ratios (C_b/T) from 0.2 to 0.8. In addition, P_o was nearly independent of the D/T ratio. (data shown in Appendix Table A.2.). These results are similar to those of Armenante et al. (1999).

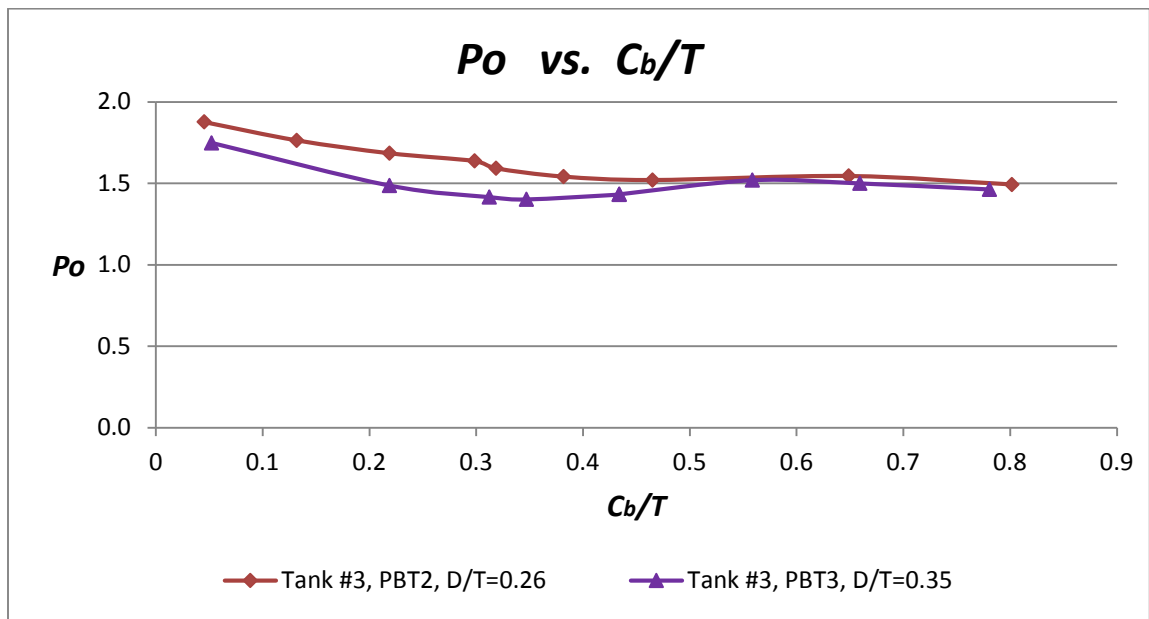

Figure 3.4 Power Number, P_o for different C_b/T , $H/T=1$, $D/T=0.26$ or 0.35 , calculated from both experimental data ($N \geq 450$ rpm).

3.3 Solids Suspension in Stirred Baffled Tanks at Different Submergence Ratios and Clearance Ratios

In Section 3.1 and 3.2, the effect of S_b/D on Power Number in stirred baffled tanks with different geometrical variables (C_b/T , D/T) was described. In this section, the effect of C_b/T ratio and S_b/D on the performance of the same mixing systems to achieve complete solid suspension was studied.

Experiments were carried out in the same PBT #2 described in Section 2.1. The liquid phase was water and spherical glass beads (0.5% wt/wt; $\rho=2500 \text{ m}^3/\text{kg}$; diameter 150 μm to 200 μm) were used. The minimum agitation speed required for complete off-bottom particle suspension, N_{js} , was determined visually (as described in Chapter 2.3).

The main objective here was to characterize the effect of impeller submergence ratio (S_b/D) on N_{js} for stirred vessels with different C_b/T and different D/T . N_{js} was obtained for: (1) $H/T=1$ and different D/T and C_b/T ratios; (2) $C_b/T=0.30$ and different D/T and S_b/D ratios.

3.3.1 Effect of C_b/T on Minimum Agitation Speed (N_{js}) for Complete Off-Bottom Solid Suspension for $H/T=1$ and Different D/T

Figure 3.5(a) shows the minimum agitation speed measured at two different impeller D/T ratios (0.31 and 0.40) and same liquid level ($H/T=1$) as a function of the impeller off-bottom clearance ratio (C_b/T). Figure 3.5(a) also shows that glass beads could be suspended at a lower impeller agitation speed when the D/T ratio increased.

Sharma and Shaikh (2003) illustrated the relationship of minimum agitation speed for complete off-bottom solids suspension with impeller clearance: at low C/T where the impeller is very close to the tank bottom, the minimum agitation speed and the relevant

power remains constant. Figure 3.5(a) and Figure 3.5(b) shows the same outcome. Figure 3.7 shows that the power number at the minimum agitation speed for complete off-bottom solids suspension is inversely proportional to the impeller off-bottom clearance ratios (C_b/T) at low C/T . (Data shown in Appendix Table A.3)

Figure 3.5(a) and (b) also show that D/T is also affects the minimum agitation speed but that the minimum power for complete off-bottom solid suspension (P_{js}) is independent on D/T .

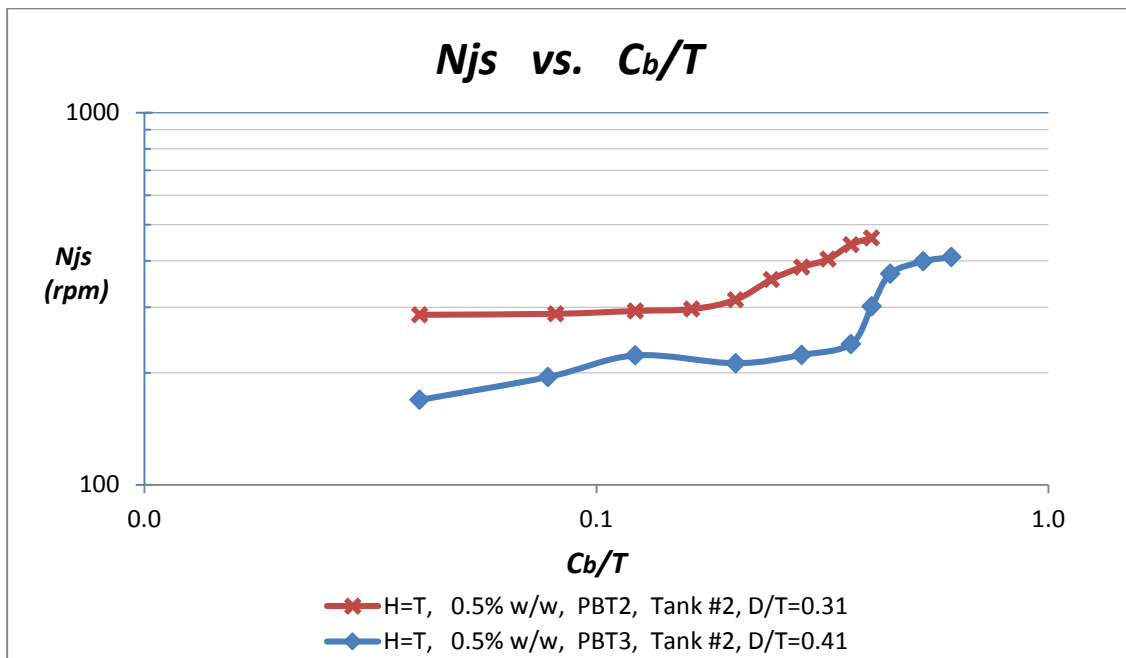

Figure 3.5(a) Minimum agitation speed for complete off-bottom solid suspension (N_{js}) as a function of impeller off-bottom clearance ratios (C_b/T) at different D/T ratios.

Figure 3.5(b) The minimum power for complete off-bottom solid suspension (P_{js}) as a function of impeller off-bottom clearance ratios (C_b/T) at different D/T ratios.

3.3.2 Effect of S_b/D on Minimum Agitation Speed (N_{js}) for Complete Off-Bottom Solid Suspension for $C_b/T=0.30$ and Different D/T Ratios

Figure 3.6 shows the minimum agitation speed measured for $C_b/T=0.30$ or 0.31 at different impeller D/T ratios as a function of the impeller submergence ratio (S_b/D). (Data shown in Appendix Table A.4.) Figure 3.6 also shows that solids could be suspended at a lower agitation speed when D/T ratios increased. A similar phenomenon has been reported by Motamedvaziri and Armenante (2012) in a baffled tank with a disk turbine (DT). For any D/T ratio, there is a critical impeller submergence (S_b/D value), below which solid suspension becomes impossible, irrespective of how high N is, although the impeller is still fully submerged. Solids could be suspended only above this critical S_b/D value

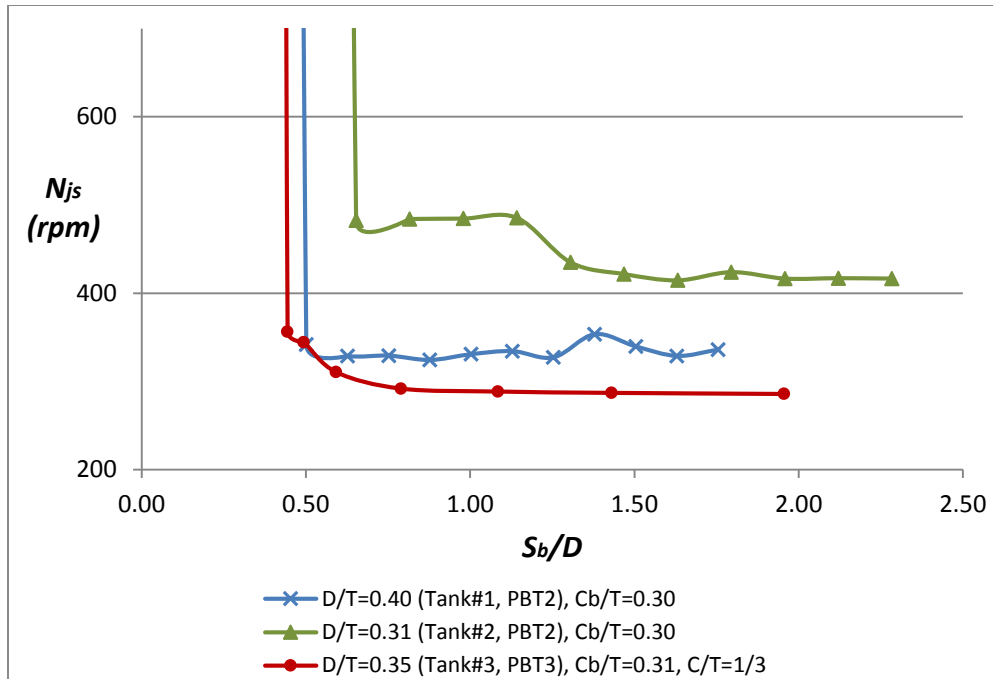

Figure 3.6 Minimum agitation speed for complete off-bottom solid suspension (N_{js}) as a function of impeller submergence ratio for $C_b/T=0.30$ or 0.31 and different D/T ratios.

Figure 3.6 shows that there is a critical liquid level below which that solids could be suspended for the 6-PBT case as well, i.e., for an axial impeller. For Tank#1 and Tank#2, the minimum level for solid suspension was $S_b/D=0.5$ and 0.6 for $D/T=0.40$ and 0.31 , respectively.

For Tank #3 with PBT #3, the minimum level for solid suspension was $S_b/D=0.44$. The range of the critical submergence ratios are exactly the same as those have been get in Section 3.1 as the power number decreased drastically, shown in Figure 3.7.

The results obtained here for the critical agitation speed for solid suspension confirm that a stirred baffled tank operating at low impeller submergence is more likely to experience impeller flooding conditions. The impeller loses its ability to provide sufficient liquid for the entire loop and thus lose complete off-bottom solid suspension.

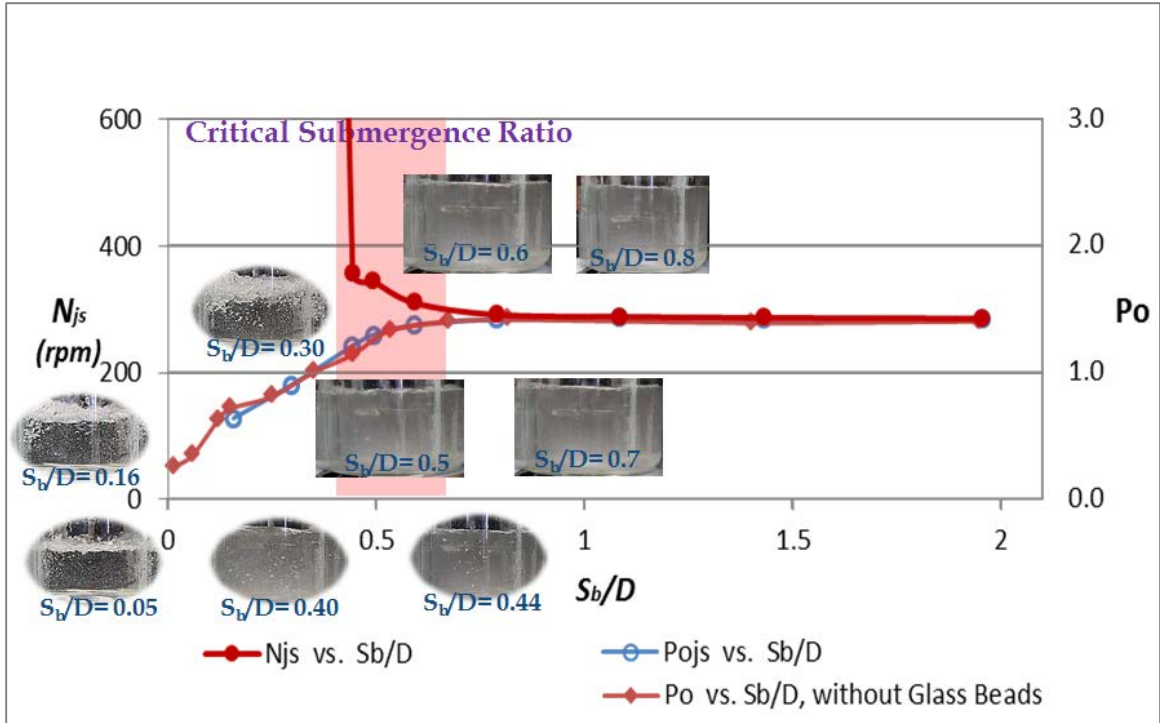

Figure 3.7 Minimum agitation speed and the relative power number for complete off-bottom solid suspension (N_{js}) as a function of impeller submergence ratio for $C/T=1/3$. (And the power number, P_o , for different S_b/D in tank #3 with PBT3 without glass beads gotten in Section 3.1.)

CONCLUSION

In this work, the effect of the S_b/D ratio and the C_b/T ratio, as well as D/T ratio on the impeller Power Number for six-blade, 45° pitch-blade turbine impellers in flat bottom baffled tanks was studied.

When the impeller submergence ratio, S_b/D , is higher than a critical value $(S_b/D)_{cr}$, the impeller power number, P_o , is constant and nearly independent on impeller submergence. However, below this critical submergence ratio, the impeller Power Number was found to decrease drastically. In this range, the impeller power number was almost directly proportional to S_b/D when for $S_b/D < (S_b/D)_{cr}$. For $H=T$, P_o was nearly constant for different impeller off-bottom clearance ratios (C_b/T) from 0.2 to 0.8. P_o is also affected by the D/T , but it is mainly affected by the S_b/D and the C_b/T .

For each tank system and D/T , there is a minimum value of the S_b/D to achieve complete off-bottom solids suspension. This value is the same value at which P_o was shown become a function of S_b/D . For S_b/D higher than critical value, P_o was constant and independent on S_b/D ; however, when S_b/D was lower than the critical value, P_o decreased and became almost directly proportional to the S_b/D ratio. The results obtained here for the minimum agitation for solid suspension, N_{js} , confirm that a stirred vessel operating at low impeller submergence is more likely to experience impeller flooding conditions where the impeller loses its ability to provide adequate liquid pumping, thus resulting in poor mixing performance.

APPENDIX

Data

The mainly data used in Chapter 3 are shown in below.

Table A.1 Power number, Po , for different S_b/D or S_b/T ratios in different combination of impellers and stirred baffled tanks at $C/T=1/3$

(a) Power Number for $D/T=0.41$, Tank #2, PBT3

S_b/D	S_b/T	Tank	Impeller	N (rpm)	Po	Re	Fr
1.68	0.69	Tank #2	PBT3	351	1.377	68799	0.463
1.22	0.50	Tank #2	PBT3	401	1.379	68796	0.463
0.71	0.29	Tank #2	PBT3	401	1.349	68831	0.463
0.53	0.22	Tank #2	PBT3	402	1.316	68875	0.464
0.43	0.18	Tank #2	PBT3	402	1.241	68695	0.461
0.34	0.14	Tank #2	PBT3	401	0.855	68572	0.460
0.24	0.10	Tank #2	PBT3	400	0.691	68584	0.460
0.14	0.06	Tank #2	PBT3	400	0.497	68674	0.461
0.04	0.02	Tank #2	PBT3	401	0.202	68694	0.461

(b) Power Number for $D/T=0.35$, Tank #3, PBT3

S_b/D	S_b/T	Tank	Impeller	N (rpm)	Po	Re	Fr
